Software Clustering

Decomposing a large software system into meaningful subsystems

- Developers create sophisticated applications that are complex and involve a large number of interconnected components.
- **Result**: Program understanding is difficult
- Goal: Use automated techniques to help developers understand the structure of software systems.

Common Problems

- Creating a good mental model of the structure of a complex system.
- Keeping a mental model consistent with changes that occur as the system evolves.
- These problems are exacerbated by:
 - Non-existent or inconsistent design documentation
 - High rate of turnover among IT professionals
- **Assumption**: Understanding the structure of a software system is valuable for maintainers.

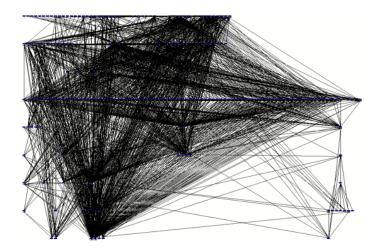

Solutions

- Automatic: Use software clustering techniques to decompose the structure of software systems into meaningful subsystems.
 - Subsystems help developers navigate through the numerous software components and their interconnections.
- Manual: Use notations such as UML to specify the software structure.

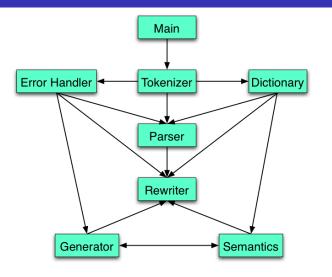

Why is clustering useful?

- Helps new developers create a mental model of the software structure.
- Especially useful in the absence of experts or accurate design documentation.
- Helps developers understand the structure of legacy software.
- Enables developers to compare the documented structure with the automatically created (actual) structure.

Example (before)

Example (after)

Software Clustering Challenges

- There are many ways to partition a set of entities into clusters.
- How do we create efficient algorithms to find partitions that are representative of a system's structure?
- How do we distinguish between good and bad partitions?

How Hard is this Problem?

• The number of partitions of *n* objects into *k* clusters is:

$$S_{n,k} = \frac{1}{k!} \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} j^n$$

- The number of ways to partition a set of *n* objects is: $B_n = \sum_{k=1}^n S_{n,k}$
- This function grows exponentially with respect to *n*. Some values:

1	5	10	15	20
1	52	115,975	1,382,958,545	51,724,158,235,372

Some solutions

- Enumerating every possible partition of the software structure graph is not practical.
- Heuristics can be used to reduce the number of partitions:
 - Searching algorithms
 - Knowledge about the source code
 Names, directory structure, designer input
 - Remove entities that provide little structural value
 Libraries, omnipresent nodes
- Result is sub-optimal, but often adequate.

Software Clustering Research

Clustering Techniques

- Clustering Procedures/Functions into Modules
- Clustering Modules/Classes into Subsystems
- Evaluating clustering algorithms
 - Measuring distance between partitions
 - Algorithm stability

- There are many different clustering techniques, but they all need to consider:
 - Representation: The entities and relationships to be clustered
 - **Similarity**: What determines the degree of similarity between the software entities
 - Algorithms: Algorithms that use the similarity measurement to make clustering decisions

Representation

Similarity

There are many choices based on the desired granularity of recovered system design

- Entities may be variables/procedures or modules/classes.
- · What types of relationships will be considered?
- · Will the relationships be weighted?

- Similarity measurements are used to determine the degree of similarity between a pair of entities
- Different types:
 - · Association coefficients: Based on common features that exist (or do not exist) between a pair of entities · Most common type of similarity measurement
 - Distance measures: Measure of the degree of dissimilarity between entities.

Similarity Measurements

- Assume that every entity is expressed in terms of binary features, TRUE denoting the existence of a feature.
- We can then define:
 - a: Number of common features in entity i and entity j
 - b: Number of features unique to entity i
 - c: Number of features unique to entity j
 - d: Number of features absent in both entity i and entity j

Association Coefficients

 Association co-efficients can be defined based on these values:

 $\overline{2a+b+c}$

Simple Matching coefficient	$rac{a+d}{a+b+c+d}$
Jaccard coefficient	<u>a</u> a+b+c
Sorensen coefficient	$\frac{2a}{2a+b+a}$

Agglomerative hierarchical algorithm

- Start by creating one cluster for each object
- Join the two most similar objects into one cluster
- Continue joining the two most similar objects/clusters until everything is in one cluster
- What you get is a dendrogram...

Dendrogram example

Cut height

- By choosing to "cut" the dendrogram at a particular height, we can create a partition of the set of objects, e.g. a cut height of 0.45 in the previous example would give us 3 clusters
- Finding an appropriate cut height is a tough problem
- Heuristics, such as the number of clusters, are usually employed
- How to determine the similarity between two already formed clusters (or an object and a cluster)
- Many possibilities
 - Minimum of all pair-wise similarities
 - Maximum of all pair-wise similarities
 - · Weighted or unweighted averages

Assignment tool: aa

- The aa tool allows to run any version of the agglomerative algorithms described before
- Example: aa input.mbd contain.rsf -c0.4 -s1 -a2
 - Cluster the objects in <code>input.mbd</code> using a cut-height of 0.4, the Simple Matching Coefficient, and the Weighted Average Algorithm
- The .mbd stands for "market basket data". You can transform from RSF to MBD with: unitrans input.rsf output.mbd

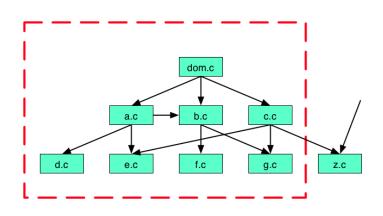

Pattern-based software clustering

- Manual decompositions of large pieces of software often contain certain types of subsystems
- A software clustering algorithm that creates clusters based on these patterns would have a better chance of creating a decomposition that can help system comprehension
- These clusters can also have better names (based on the pattern they were derived from) as well as a more manageable number of contents

The ACDC algorithm

- A skeleton of the decomposition is created based on the identified patterns
- Entities not clustered this way are assigned to the cluster that they exhibit the largest connectivity to
- Experiments with large systems have shown that the skeleton usually contains at least half the system entities

Example pattern: Subgraph Dominator

Update rule

- The acdc tool is an implementation of this algorithm
- Example:

acdc input.rsf output.rsf -125

- Cluster the objects in input.rsf with a maximum size of 25 for the Subgraph Dominator pattern
- If one can express the desired properties of a clustering as a formula, then the problem of clustering is reduced to that of finding the decomposition that optimizes the value of the formula
- A typical goal is to maximize cohesion and minimize coupling

Bunch

Bunch attempts to maximize the value of the MQ function

$$MQ = \begin{cases} \frac{\sum_{i=1}^{k} A_i}{k} - \frac{\sum_{i,j=1}^{k} E_{i,j}}{\frac{k(k-1)}{2}} & k > 1\\ A_1 & k = 1 \end{cases}$$

where $A_i = \frac{\mu_i}{N_i^2}$ and $E_{i,j} = \begin{cases} 0 & i = j \\ \frac{\epsilon_{i,j}}{2N_iN_j} & i \neq j \end{cases}$

 N_i : the number of entities in cluster *i* μ_i : the number of intra-edges in cluster *i* $\epsilon_{i,i}$: the number of inter-edges between clusters *i*

and j

Assignment tool: bunch

- Bunch is an interactive tool written in Java
- Input is in a format that is exactly like RSF except that the first token is missing, i.e. only one type of relationship is assumed
- Output is in a format called SIL that can be translated to RSF (see webpage)

Bunch

- Finding the optimal clustering based on this formula is impractical
 - Exhaustive search is not recommended for more than 15 entities
- Bunch employs hill climbing and genetic algorithms to find approximate solutions

Other ideas

- The literature contains many more ideas for clustering algorithms
- Data mining techniques as well as mathematical tools such as concept analysis have been used for clustering purposes
- Using naming or ownership information has also been shown to improve clustering results
